Singularities of the geodesic flow on surfaces with pseudo-Riemannian metrics

A.O. Remizov* and F. Tari†

May 26, 2015

Abstract

We consider a pseudo-Riemannian metric that changes signature along a smooth curve on a surface, called the discriminant curve. The discriminant curve separates the surface locally into a Riemannian and a Lorentzian domain. We study the local behaviour and properties of geodesics at a point on the discriminant where the isotropic direction is tangent to the discriminant curve.

1 Introduction

The work in this paper is a part of an ongoing research on understanding the geometry of surfaces endowed with a signature varying metric (see, for example, [9, 10, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 24, 28, 32, 33]). We consider here the behavior of geodesics on a surface S endowed with a pseudo-Riemannian metric given in local coordinates by

$$ds^2 = a(x,y)\,dx^2 + 2b(x,y)\,dxdy + c(x,y)\,dy^2 \tag{1.1}$$

where the coefficients a, b, c are smooth (that means C^∞ unless stated otherwise) functions on an open set $U \subset \mathbb{R}^2$.

We assume in all the paper that the discriminant function $\Delta(x,y) = (ac - b^2)(x,y)$ vanishes on a regular curve $\mathscr{D}$, which is called *signature changing curve* or simply *discriminant curve* of the metric (1.1). The discriminant curve $\mathscr{D}$ separates (at least, locally) the surface S into a Riemannian ($\Delta > 0$) and a Lorenzian ($\Delta < 0$) domain.

Key Words and Phrases. Pseudo-Riemannian metrics, Geodesics, Singular points, Normal forms.

At any point in the Lorentzian domain, there are two *lightlike* or *isotropic* directions that consist of vectors with zero length and there is one double isotropic direction at any point on $\mathscr{D}$. The *isotropic curves* are integral curves of the equation

$$a(x,y)\,dx^2 + 2b(x,y)\,dxdy + c(x,y)\,dy^2 = 0. \tag{1.2}$$

Isotropic curves are geodesics (except in the case below) in the metric (1.1) when defined, for instance, as extremals of the action functional (the arc-length parametrization is not defined for these curves), see [22]. A non-isotropic geodesic is called *timelike* (*spacelike*) if $ds^2 > 0$ ($ds^2 < 0$) along the geodesic. The exception is when the isotropic curve coincides with the discriminant curve $\mathscr{D}$ and is a *singular solution* of equation (1.2), i.e., it is the envelop of one-parameter family of isotropic curves. This is the case Z (Table 1) and the reason why the singular solution is not a geodesic is explained in Appendix B.

When the unique isotropic direction is transverse to $\mathscr{D}$, the isotropic curves form a family of cusps (configuration C in Figure 1). At points where the isotropic direction is tangent to $\mathscr{D}$, the isotropic curves have generically one of the configurations D_s, D_n, D_f in Figure 1. Finally, the configuration Z in Figure 1 occurs in the case when the isotropic direction is tangent to $\mathscr{D}$ at all points on $\mathscr{D}$. (See Proposition 2.2 for more details.)

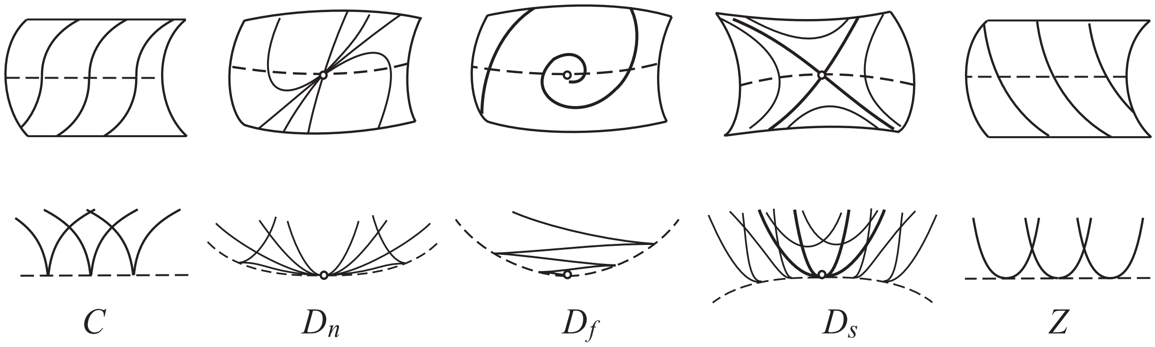

Figure 1: Top figures represent the integral curves of the field (2.2) on the isotropic surface $\mathscr{F}$. The bottom figures represent their projections to S, i.e., isotropic geodesics. The dashed lines represent the criminant (in the top figures) and the discriminant curve (in the bottom figures).

The geodesic flow generated by the metric (1.1) has singularities at every point $q \in \mathscr{D}$. The geodesics cannot pass through $q \in \mathscr{D}$ in an arbitrary tangent direction but only in certain directions said to be *admissible*, and the isotropic direction is always one of them. Singularities of geodesic flow at generic points $q \in \mathscr{D}$ (excluding isolated points) are studied in [10, 21, 22]. The excluded isolated points are the following:

(a) points where the isotropic direction is tangent to $\mathscr{D}$,

(b) points of intersection of $\mathscr{D}$ with the closure of the parabolic set of S.

In this paper, we complete the study in [10, 21, 22] for the case (a). We give in Theorems 3.2 and 3.3 the configurations of the geodesic in case (a) that correspond to the configurations D_s and D_n, D_f of the isotropic geodesics, respectively. We start our study with the configuration Z (Theorem 3.1), which is not generic. However, it provides a graphical illustration of some properties common with the cases D_s, D_n, D_f (for instance, there are no geodesics outgoing from the point of interest to the Lorenzian domain).

In Appendix A we recall some results on local normal forms of resonant and non-resonant vector fields that we use in the paper. Finally, in Appendix B we briefly consider naturally parametrized geodesics defined as extremals of the action functional.

2 Isotropic curves and geodesics

As the discriminant curve $\mathscr{D}$ is supposed to be a regular curve, the coefficients a, b, c of the metric (1.1) cannot vanish simultaneously at any point in a neighborhood of $\mathscr{D}$. We assume, without loss of generality, that near the point of interest the coefficient $c(x, y) > 0$ and write equation (1.2) as the implicit differential equation

$$F(x, y, p) := c(x, y)p^2 + 2b(x, y)p + a(x, y) = 0, \tag{2.1}$$

where $p = dy/dx$ is the non-homogeneous coordinate in the projective tangent bundle PTS. At any point $q = (x, y)$ in the Lorenzian domain ($\Delta < 0$), equation (2.1) has two simple real roots which correspond to the pair of transversal isotropic directions at q. At any $q \in \mathscr{D}$, equation (2.1) has a double root $p_0(q) = -\frac{b}{c}(q)$, which corresponds to the unique isotropic direction at q. Generically, the direction p_0 is transverse to $\mathscr{D}$ at almost all points while tangency (of the first order) can occur at isolated points on $\mathscr{D}$ only.

In the (x, y, p)-space, equation (2.1) defines a surface $\mathscr{F}$ called the *isotropic surface* of the metric (1.1). On $\mathscr{F}$ is defined a direction field which is the intersection of the contact planes $dy = p\,dx$ with the tangent planes of $\mathscr{F}$. This direction field is parallel to the vector field

$$\frac{1}{2}F_p\partial_x + \frac{1}{2}pF_p\partial_y - \frac{1}{2}(F_x + pF_y)\partial_p. \tag{2.2}$$

Formula (2.2) differs from what is generally used by the factor $\frac{1}{2}$. This is for convenience in the computations carried out in this paper.

Although the vector field (2.2) is defined in the (x, y, p)-space, we will consider it only on the isotropic surface $\mathscr{F}$ which is an invariant surface of (2.2). The isotropic curves are the projections of the integral curves of (2.2) on $\mathscr{F}$ to the (x, y)-plane along the p-direction, called *vertical.* The set of points on the surface $\mathscr{F}$ where the projection $\pi\colon \mathscr{F} \to \mathbb{R}^2$ is singular (i.e., where $F = F_p = 0$) is called the *criminant* of equation (2.1). That is, the criminant consists of the points $(q, p_0(q))$ with $q \in \mathscr{D}$. The projection of the criminant on the (x, y)-plane is the discriminant curve $\mathscr{D}$.

Remark 2.1 In a neighborhood of any point $q_* \in \mathscr{D}$, there exist local coordinates where the metric is diagonal (i.e., $b \equiv 0$) and the discriminant curve $\mathscr{D}$ is given by the equation $a(x, y) = 0$. Then $p_0(q) \equiv 0$ at all $q \in \mathscr{D}$, the derivatives a_x, a_y do not vanish simultaneously (since Δ is a regular function) and $c(q_*) \neq 0$. We assume, without loss of generality, that $c(q_*) > 0$.

As in Riemannian geometry, non-parametrized geodesics in pseudo-Riemannian metrics can be defined as extremals of the length functional or as extremals of the action functional after ignoring the natural parametrization, see [22]. In the fist case, a special problem arises. The Lagrangian of the length functional has the form $L = \sqrt{F}$, where F defined in (2.1) vanishes on the isotropic surface $\mathscr{F}$, and the corresponding Euler–Lagrange equation is not defined on $\mathscr{F}$. Also, the arc-length parametrization is not defined for isotropic curves. However, such a problem does not arise if we define geodesics as extremals of the action functional.

The standard projectivization $TS \to PTS$, which means forgetting the natural parametrization of geodesics) transforms the field (2.2) into a direction field on PTS parallel to

$$2\Delta\partial_x + 2p\Delta\partial_y + M\partial_p, \tag{2.3}$$

where M is a cubic polynomial in p given by $M(q,p) = \sum\limits_{i=0}^{3} \mu_i(q)p^i$ with the coefficients

$$\begin{aligned}
\mu_0 &= a(a_y - 2b_x) + a_x b,\\
\mu_1 &= b(3a_y - 2b_x) + a_x c - 2ac_x,\\
\mu_2 &= b(2b_y - 3c_x) + 2a_y c - ac_y,\\
\mu_3 &= c(2b_y - c_x) - bc_y.
\end{aligned}$$

See [22] for more details. By Theorem 1 in [10], the isotropic surface $\mathscr{F}$ is an invariant surface of the field (2.3), and integral curves of the 2-distribution $dy = pdx$ lying on $\mathscr{F}$ are integral curves of (2.3). Hence all isotropic curves (except for those that coincide with $\mathscr{D}$) with an appropriate choice of parametrization are extremals of the action functional. Consequently, they are geodesics.

Consider the field (2.3) at a point (q, p), $q \in \mathscr{D}$. Since $\Delta(q) = 0$, the vertical line passing through q is an integral curve of (2.3). If $M(q, p) \neq 0$, it is the unique integral curve of (2.3) passing through (q, p). The projection of this curve to the (x, y)-plane along the p-direction is the point q, so is not a geodesic. Hence geodesics can pass through a point $q \in \mathscr{D}$ only at *admissible* tangential directions p given by $M(q,p) = 0$. One can show (see [21]) that

$$M(q,p) = \frac{1}{3}(p - p_0)(2(\Delta_x + p\Delta_y) + M_p), \quad \forall\, q \in \mathscr{D}. \tag{2.4}$$

From (2.4), it follows that the isotropic direction p_0 is always a root of the cubic polynomial $M(q,p)$. Furthermore, if p is a double root of $M(q,p)$, then the direction p is tangent to the curve $\mathscr{D}$ at q. Indeed, if $p \neq p_0$, then substituting $M = M_p = 0$ in (2.4), we get $\Delta_x + p\Delta_y = 0$. If $p = p_0$, then differentiation (2.4) with respect to p and substitution $M = M_p = 0$ yields $\Delta_x + p_0\Delta_y = 0$.

Let K denote the Gaussian curvature of $S \setminus \mathscr{D}$. (Generically $K(q) \to \infty$ as $q \to \mathscr{D}$.) The function $K_1 = \Delta^2 K$ is well defined and is smooth on the whole surface S and is an isometric invariant. The set $K_1 = 0$ is the closure of the parabolic set of S.

Before giving some properties of M, we introduce the following notation: $p_0 \pitchfork \mathscr{D}$ means that the direction p_0 is transverse to the curve $\mathscr{D}$, $p_0 \| \mathscr{D}$ and $\operatorname{ord}(p_0 \| \mathscr{D}) = 1$ mean respectively that p_0 is tangent to $\mathscr{D}$ and has first order tangency with $\mathscr{D}$. Finally, $(\varepsilon_1, \varepsilon_2)$ and $(\lambda_1, \lambda_2, 0)$ denote the spectrums of the linear parts of the vector fields (2.2) and (2.3) at the point (q, p_0), $q \in \mathscr{D}$, respectively.

Proposition 2.1 *Let $q \in \mathscr{D}$, then the following statements hold.*

(i) *The cubic polynomial $M(q,p)$ has a unique real root p_0 if and only if $K_1(q) < 0$.*

(ii) *p_0 is a simple root of $M(q,p)$ if and only if $p_0 \pitchfork \mathscr{D}$ at q, or equivalently, the p-component of the field (2.2) does not vanish at (q, p_0).*

(iii) *$M(q,p)$ has three distinct real roots p_0, p_1, p_2 if and only if $K_1(q) > 0$ and $p_0 \pitchfork \mathscr{D}$ at q.*

(iv) *$M(q,p)$ has a double root $p_1 = p_2 \neq p_0$ if and only if $K_1(q) = 0$ and $p_0 \pitchfork \mathscr{D}$ at q. The double non-isotropic direction p_1 is tangent to $\mathscr{D}$ at q.*

(v) *$M(q,p)$ has a double root $p_0 = p_1 \neq p_2$ if and only if $K_1(q) > 0$ and $p_0 \| \mathscr{D}$ at q.*

(vi) *The isotropic direction $p_0 \| \mathscr{D}$ at q if and only if (2.2) vanishes at (q, p_0). Then $\varepsilon_1 + \varepsilon_2 \neq 0$. Moreover, $\operatorname{ord}(p_0 \| \mathscr{D}) = 1$ if and only if $\varepsilon_1, \varepsilon_2 \neq 0$, that is, (q, p_0) is a node, saddle or focus of (2.2).*

(vii) *If $p_0 \| \mathscr{D}$ at all points on $\mathscr{D}$, then the p-component of the field (2.2) vanishes on the criminant. Hence the criminant consists of singular points of (2.2) with one of the eigenvalues $\varepsilon_1, \varepsilon_2$ equal to zero and the other is distinct from zero.*

(viii) *If (q, p) is a singular point of the field (2.3), then $\lambda_1 = 2(\Delta_x(q) + p\Delta_y(q))$ and $\lambda_2 = M_p(q, p)$.*

Proof It is convenient to take the point q to be the origin and choose the local coordinates in Remark 2.1. Then (2.4) becomes

$$M(0,p) = -cpQ(p), \quad Q(p) = c_x p^2 - 2a_y p - a_x,$$

the quadric polynomial Q has discriminant $\delta = a_x c_x + a_y^2$. Using the Brioschi formula [30], we get $K_1(0) = c(0)\delta(0)/4$. Since the coefficient c is positive, it follows that $K_1(0)$ and $\delta(0)$ have the same sign.

For (i), the cubic polynomial $M(0,p)$ has only one real root p_0 if and only if $\delta(0) < 0$ or $\delta(0) = 0$ and $p_0 = 0$ is a double root of $Q(p)$. In the second case we have $a_x(0) = 0$, which together with $\delta(0) = 0$ gives $a_x(0) = a_y(0) = 0$. This contradicts the assumption that $\Delta = ac$ is regular at the origin.

The proof of (ii) follows by direct calculation. For (iii), $M(0,p)$ has three distinct real roots if and only if $Q(p)$ has two distinct real roots $p_1 \neq p_2$ and $p_0 \neq p_1, p_2$. Clearly, these conditions are equivalent to $K_1(0) > 0$ and $p_0 \pitchfork \mathscr{D}$. The statement (iv) follows from (2.4). The proofs of the remaining statements follow by direct calculations and are omitted. $\square$

We have the following about isotropic geodesics.

Proposition 2.2 *Let $q \in \mathscr{D}$, then the following statements hold.*

- C. *If $p_0 \pitchfork \mathscr{D}$ at $q \in \mathscr{D}$, then the germ of (2.1) at (q, p_0) is smoothly equivalent to $p^2 = x$ (Cibrario normal form).*
- D. *If $\operatorname{ord}(p_0 \| \mathscr{D}) = 1$ at $q \in \mathscr{D}$ and between the eigenvalues $\varepsilon_1, \varepsilon_2$ there are no non-trivial resonances*

$$s_1\varepsilon_1 + s_2\varepsilon_2 = \varepsilon_j, \quad s_1, s_2 \in \mathbb{Z}_+, \quad s_1 + s_2 \geq 1, \quad j = 1, 2, \tag{2.5}$$

then the germ of (2.1) at (q, p_0) is smoothly equivalent to $p^2 = y - \varepsilon x^2$, where $\varepsilon = \varepsilon_1\varepsilon_2 \neq 0, \frac{1}{16}$ (Dara-Davydov normal form). The excluded values $\varepsilon = 0, \frac{1}{16}$ correspond the cases when $\varepsilon_1\varepsilon_2 = 0$ or $\varepsilon_1 = \varepsilon_2$.

- Z. *If $p_0 \| \mathscr{D}$ at all points on $\mathscr{D}$, then the germ of (2.1) at (q, p_0) is smoothly equivalent to $p^2 = y$ (Clairaut normal form).*

Proof The proof of the case C in the smooth category can be found in [1] (the earlier proof in the analytic category can be found in [5]). The proof of the case D can be found in [6] or [7]. The proof of the case Z can be found in [8] (it can be also proved using the approach in [1] for the case C). $\square$

Remark 2.2 It is worth observing that Cibrario normal form $p^2 = x$ (case C in Proposition 2.2) is valid in the analytic category, while Dara-Davydov normal form $p^2 = y - \varepsilon x^2$ (case D in Proposition 2.2) is not; see [18].

Table 1 combines the information in Propositions 2.1 and 2.2 and gives a classification of singularities of the geodesic flow generated by the metric (1.1). The first column contains the names of the singularities. The singularities C_i, $i = 1, 2, 3$ and D_s, D_n, D_f are topologically stable, while the singularity Z is not and has infinite codimension. Moreover, the topological equivalence eliminates the modulus parameter ε in the normal form $p^2 = y - \varepsilon x^2$ in each of three cases D_s, D_n, D_f (see [6, 7]). The second and third columns are the conditions for the occurrence of the singularities. The last column gives the normal forms of the equation of the isotropic geodesics (2.1), see also Figure 1.

Table 1: Classification of singularities of the geodesic flow.

case	condition 1	condition 2	real roots of $M(q,p)$	normal form of (2.1)
C_1	$K_1(q) < 0$	$p_0 \pitchfork \mathscr{D}$ at q	p_0 (simple)	$p^2 = x$
C_2	$K_1(q) = 0$	$p_0 \pitchfork \mathscr{D}$ at q	$p_0 \neq p_1 = p_2$	$p^2 = x$
C_3	$K_1(q) > 0$	$p_0 \pitchfork \mathscr{D}$ at q	p_0, p_1, p_2 (all simple)	$p^2 = x$
D_s	$K_1(q) > 0$	$\operatorname{ord}(p_0 \Vert \mathscr{D}) = 1$ at q (2.2) is a saddle at (q, p_0) on $\mathscr{F}$	$p_0 = p_1 \neq p_2$	$p^2 = y - \varepsilon x^2$ $\varepsilon < 0$
D_n	$K_1(q) > 0$	$\operatorname{ord}(p_0 \Vert \mathscr{D}) = 1$ at q (2.2) has node at (q, p_0) on $\mathscr{F}$	$p_0 = p_1 \neq p_2$	$p^2 = y - \varepsilon x^2$ $0 < \varepsilon < \frac{1}{16}$
D_f	$K_1(q) > 0$	$\operatorname{ord}(p_0 \Vert \mathscr{D}) = 1$ at q (2.2) is a focus at (q, p_0) on $\mathscr{F}$	$p_0 = p_1 \neq p_2$	$p^2 = y - \varepsilon x^2$ $\varepsilon > \frac{1}{16}$
Z	$K_1(q) > 0$	$p_0 \Vert \mathscr{D}$ at $\forall q \in \mathscr{D}$	$p_0 = p_1 \neq p_2$ $\forall q \in \mathscr{D}$	$p^2 = y$

The following results about the behavior of the geodesics outgoing from a point $q \in \mathscr{D}$ with the tangential direction p being a simple root of $M(q,p)$ are established in [21]. We start with geodesics passing through a point on the discriminant curve $\mathscr{D}$ with non-isotropic admissible directions. It covers all the cases in Table 1 except C_2.

Theorem 2.1 ([21]) *Let p_i, $i = 1$ or 2, be a non-isotropic simple real root of the cubic polynomial $M(q,p)$ at $q \in \mathscr{D}$. Then to the admissible direction p_i corresponds a unique smooth geodesic passing through the point q.*

The next theorem is proved in [21] for the cases C_1, C_3. However, from its proof it follows that it is also valid in the case C_2, since it deals with the root p_0 only. Theorems 2.1 and 2.2 give complete information about the configuration of geodesics outgoing from a point $q \in \mathscr{D}$ with all possible admissible directions in the cases C_1, C_3.

Theorem 2.2 ([21]) *Suppose that the isotropic root p_0 of $M(q,p)$ at $q \in \mathscr{D}$ is simple. Then to p_0 corresponds a one-parameter family Γ_0 of geodesics outgoing from the point q. There exist smooth local coordinates centered at 0 such that the discriminant curve $\mathscr{D}$*

coincides with the x-axis, the isotropic direction $p_0(q) = \infty$ and the geodesics $\gamma_\alpha^\pm \in \Gamma_0$ are semi-cubic parabolas

$$x = \alpha\tau^3 X_\alpha(\tau), \quad y = \tau^2 Y_\alpha(\tau), \quad \alpha \in \mathbb{R}^+, \tag{2.6}$$

where X_α, Y_α are smooth functions, $X_\alpha(0) = 1$, $Y_\alpha(0) = \pm 1$. Here the superscripts $+$ and $-$ distinguish geodesics outgoing from the origin in the semiplanes $y > 0$ and $y < 0$, respectively. The family (2.6) contains the three types of geodesics: γ_α^+ are timelike if $\alpha > 1$, spacelike if $\alpha < 1$, isotropic if $\alpha = 1$; all γ_α^- are timelike. See Figure 2*.*

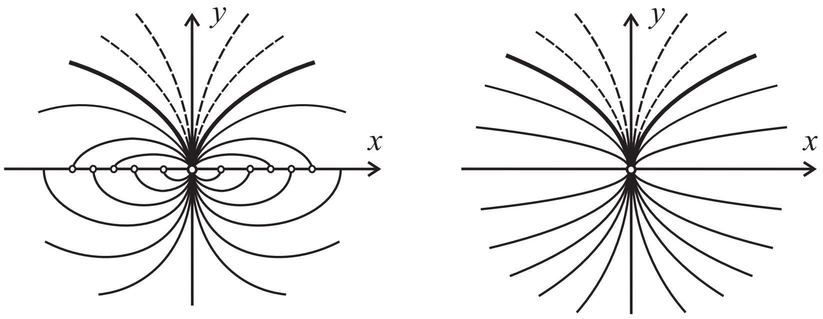

Figure 2: Two examples of configurations of the geodesics outgoing from $q \in \mathscr{D}$ in Theorem 2.2. Here the discriminant curve $\mathscr{D}$ coincides with the x-axis. Timelike, spacelike and isotropic geodesics are solid, dashed and bold solid lines, respectively.

Remark 2.3 1. For any $\alpha \neq 0$ formula (2.6) defines a semi-cubic parabola, while for $\alpha = 0$ we have the limiting case of the semi-cubic parabolas: the two branches are glued together to form the geodesics $\gamma_0^\pm$ which are the two semi-axes $y > 0$ and $y < 0$.

2. An interesting problem is to determine whether a geodesic starting from a point $q \in \mathscr{D}$ returns to the discriminant curve $\mathscr{D}$. For instance, two examples of different behavior of geodesics are presented in Figure 2. This problem is studied in [22] for metrics possessing differentiable groups of symmetries; see also [9, 15] for related work.

3 The main results

We deal here with the cases D_n, D_f, D_s and Z in Table 1 and determine the behavior of the geodesics near a point $q \in \mathscr{D}$, where the cubic polynomial $M(q, p)$ has the double root $p_0 = p_1$.

From now on, we will assume that in the cases D_n, D_s between the numbers $\varepsilon_1, \varepsilon_2, 1$ there are no non-trivial integer relations

$$\begin{aligned} &s_1\varepsilon_1 + s_2\varepsilon_2 + s_3 = \varepsilon_j, \\ &s_1\varepsilon_1 + s_2\varepsilon_2 + s_3 = 1, \end{aligned} \qquad |s| := \sum_{i=1}^{3} s_i \geq 1, \quad s_i \in \mathbb{Z}_+. \tag{3.1}$$

Clearly, this condition implies the absence of the resonances (2.5) in Proposition 2.2.

Thus in all cases D_n, D_f, D_s and Z there exist smooth local coordinates such that equation (2.1) has the normal form $p^2 = r(x,y)$, where $r(x,y) = y - \varepsilon x^2$. The cases D_n, D_f, D_s and Z correspond, respectively, to $0 < \varepsilon < \frac{1}{16}$, $\varepsilon > \frac{1}{16}$, $\varepsilon < 0$ and $\varepsilon = 0$. Then the metric (1.1) has the form

$$ds^2 = \omega(x,y)\,(r(x,y)dx^2 - dy^2) + \Theta, \quad \omega(0,0) = -1, \quad r(x,y) = y - \varepsilon x^2, \tag{3.2}$$

where ω is a smooth function and Θ is a smooth metric of the form (1.1) whose coefficients are identically zero in the Lorenzian domain. Consequently, its coefficients are infinitely flat on the discriminant curve $r(x,y) = 0$. The set of such functions is the ideal $\mathfrak{M}^\infty(r) \subset \langle r^n \rangle$ with any $n \in \mathbb{N}$ (in the ring of smooth functions).

The assumption $\omega(0,0) = -1$ can be achieved by multiplication of the metric by a non-zero constant, which does not change geodesics. Then $y > \varepsilon x^2$ (resp. $y < \varepsilon x^2$) is the Lorenzian (resp. Riemannian) domain of the surface. We shall distinguish geodesics outgoing from the origin to the region $y > \varepsilon x^2$ (resp. $y < \varepsilon x^2$) using the superscripts + (resp. −).

After dividing by appropriate factor $(-\omega + \ldots)$, the field (2.3) is

$$2\omega r\partial_x + 2p\omega r\partial_y + \bar{M}\partial_p, \tag{3.3}$$

with $\bar{M}(x,y,p) = \omega_x p^3 + (r\omega_y + 2\omega)p^2 - (r\omega_x + 2\varepsilon x\omega)p - r(r\omega_y + \omega) + \ldots$, where the dots mean terms that belong to the ideal $\mathfrak{M}^\infty(r)$.

The singular points of the field (3.3) are given by the equations $r(x,y) = 0$ and $\bar{M}(x,y,p) = 0$. On the discriminant curve $r(x,y) = 0$ and away from the origin, the cubic polynomial $\bar{M} = p(\omega_x p^2 + 2\omega p - 2\varepsilon x\omega)$ has the simple isotropic root $p_0 = 0$ and two more distinct real roots p_1, p_2 being the roots of the quadratic polynomial $\omega_x p^2 + 2\omega p - 2\varepsilon x\omega$ whose discriminant is strictly positive on $r(x,y) = 0$ away from the origin.

Hence in the cases D_n, D_f, D_s at every point on the discriminant curve except the origin there are three different admissible directions p_0, p_1, p_2, while at the origin two of them coincide: $p_0 = p_1 = 0$ and $p_2 = -2\omega/\omega_x$. In the case Z we have $p_0 = p_1 = 0$ and $p_2 = -2\omega/\omega_x$ at all points on the discriminant curve. The case $\omega_x = 0$ is also included: then $\bar{M}$ considered as a cubic polynomial over $\mathbb{R}P^1 = \mathbb{R} \cup \infty$ has a simple non-isotropic root $p_2 = \infty$.

In all cases D_n, D_f, D_s and Z, Theorem 2.1 establishes the existence of a unique smooth geodesic passing through the origin with non-isotropic admissible direction p_2, while Theorem 2.2 is not applicable for the double isotropic direction $p_0 = p_1 = 0$, since the spectrum of the linear part of the field (3.3) at the origin contains three zero eigenvalues.

To study the behavior of the geodesics passing through the origin with the double isotropic direction $p_0 = p_1 = 0$, we consider the blowing up

$$\Psi\colon (x,u,p) \mapsto (x,y,p), \quad y = \varepsilon x^2 + up^2, \quad u \in \mathbb{R}P^1 = \mathbb{R} \cup \infty. \tag{3.4}$$

The mapping Ψ is one-to-one except on the plane $\Pi = \{(x,u,p)\colon p = 0\}$, whose image is the line $\Psi(\Pi) = \{(x,y,p)\colon y - \varepsilon x^2 = p = 0\}$. The mapping Ψ is a local diffeomorphism at all points except on Π. It has an inverse defined on $\mathbb{R}^3 \setminus \Psi(\Pi)$ given by

$$\Psi^{-1}(x,y,p) = \left(x, \frac{r(x,y)}{p^2}, p\right), \quad r = y - \varepsilon x^2.$$

Observe that there are no geodesics corresponding to integral curves of the field (3.3) coinciding with the curve $\Psi(\Pi)$. Indeed, if $\Psi(\Pi)$ is an integral curve of (3.3), then the identities $y \equiv \varepsilon x^2$, $p \equiv 0$ hold. Form the first of them we have $p \equiv 2\varepsilon x$, which contradicts to the second one if $\varepsilon \neq 0$. The remaining case $\varepsilon = 0$ is more complicated, and we give the proof of this statement in Appendix B using the equation of naturally parametrized geodesic.

Away from $\Psi(\Pi)$, the map Ψ^{-1} sends the isotropic surface $\mathscr{F}$ which is an invariant surface of the field (3.3) to the plane $u = 1$. Hence, the field (3.3) corresponds to a smooth field in the (x,u,p)-space (away of Π) which has $u = 1$ as invariant plane. Taking this into account, we obtain from (3.3) and (3.4) that the last field, after dividing by the common factor p, is

$$2\omega up\partial_x + \big(pM_1 - 2\varepsilon x\omega + \ldots\big)\partial_p + (u-1)\big(2uN_1 + \ldots\big)\partial_u, \tag{3.5}$$

with

$$\begin{aligned} M_1(x,u,p) &= p(up\omega_y + \omega_x)(1-u) + \omega(2-u), \\ N_1(x,u,p) &= up^2\omega_y + p\omega_x + \omega, \end{aligned}$$

where $\omega, \omega_x, \omega_y$ are evaluated at $(x, \varepsilon x^2 + up^2)$ and the dots mean terms that belong to the ideal $\mathfrak{M}^\infty(up)$.

Since the first and second components of (3.5) vanish on the u-axis ($x = p = 0$), the u-axis is the unique integral curve of the field (3.5) passing through any point satisfying the conditions $x = p = 0$ and $u(u-1)N_1(x,u,p) \neq 0$. From $y = \varepsilon x^2 + up^2$ it follows that the map $\pi \circ \Psi(x,u,p) = (x,y)$ sends the u-axis in the (x,u,p)-space to the origin in the (x,y)-plane. Consequently, the u-axis does not correspond to a geodesic. This leads to the necessary condition $u(u-1)N_1(0,u,0) = 0$. Since $N_1(0,u,0) = \omega(0,0) \neq 0$, we get only two admissible values: $u = 0$ and $u = 1$.

Lemma 3.1 *To the admissible value $u = 0$ does not correspond any geodesic passing through the origin in the (x,y)-plane and tangent to the isotropic direction.*

Proof The germ of the field (3.5) at the origin in the (x,u,p)-space has the form (4.7) with $n=3$ (Appendix A). Indeed, its components belong to the ideal I generated by the components $\big(pM_1-2\varepsilon x\omega+\ldots\big)$ and $(u-1)\big(2uN_1+\ldots\big)$, and the center manifold W^c, given by the equations $pM_1-2\varepsilon x\omega=0$ and $u=0$, consists of the singular points of the field (3.5). The spectrum of the linear part of (3.5) at any singular point is $(\lambda_1,\lambda_2,0)$ with $\lambda_1=2\omega$ and $\lambda_2=-2\omega$, so the resonance $\lambda_1+\lambda_2=0$ holds. It follows by Theorem 4.4 (Appendix A) that the germ (3.5) is topologically equivalent to $\xi\partial_\xi-\eta\partial_\eta$. By Theorem 4.7 (Appendix A), it is smoothly orbitally equivalent to the normal form (4.15). Moreover, if the 2-jet of (3.5) is generic, it is smoothly orbitally equivalent to (4.16), that is, $\xi\partial_\xi-\eta\partial_\eta+\xi\eta\partial_\zeta$.

Any of these normal forms shows that there are only two integral curves passing through the origin, which coincide with the ξ-axis and η-axis in the normal forms coordinates. On the other hand, it is easy to see that the p-axis and u-axis are integral curves of the field (3.5) in the initial coordinates (x,u,p). Therefore, the p-axis and the u-axis are the only integral curves of the field (3.5) passing through the origin. The map $\pi\circ\Psi(x,u,p)=(x,y)$ sends the p-axis and u-axis in the (x,u,p)-space to the origin in the (x,y)-plane. □

We consider now the admissible variable $u=1$ and study the phase portrait of the field (3.5) in a neighborhood of its singular point $(x,u,p)=(0,1,0)$.

Dividing the field (3.5) by the non-vanishing germ $(2uN_1+\ldots)$ and making the affine change of variable $v=u-1$, we transform (3.5) into

$$pA(x,v,p)\partial_x+\big(\tfrac{1}{2}pB_1(x,v,p)-\varepsilon xB_2(x,v,p)\big)\partial_p+v\partial_v, \tag{3.6}$$

where A and B_1,B_2 are smooth functions such that

$$A(x,0,0)\equiv B_1(x,0,0)\equiv B_2(x,0,0)\equiv 1.$$

It is worth observing that (3.6) has an isolated singularity at the origin in the cases D_s,D_n,D_f (when $\varepsilon\neq 0$) and a non-isolated singularity in the case Z (when $\varepsilon=0$). We deal with the cases D_s,D_n,D_f and Z separately, and start with the case Z.

3.1 The case Z

Theorem 3.1 *Let S be a surface with a pseudo-Riemannian metric* (1.1) *and let $q\in\mathscr{D}$ be a point satisfying the conditions Z in Table 1. Then to the isotropic direction p_0 corresponds a one-parameter family Γ_0 of smooth geodesics outgoing from q into the Lorenzian domain, while there are no geodesics outgoing from q into the Riemannian domain.*

There exist smooth local coordinates centered at the origin such that the metric has the form (3.2) *and the geodesics $\gamma_\alpha^+\in\Gamma_0$ outgoing from the origin are*

$$y=\frac{1}{4}x^2+\alpha x^4(1+Y_\alpha(x)),\quad Y_\alpha(0)=0,\quad \alpha\in\mathbb{R}. \tag{3.7}$$

The family (3.7) *contains all three types of geodesics: timelike if* $\alpha > 0$*, spacelike if* $\alpha < 0$ *and isotropic if* $\alpha = 0$*; see* Figure 3*, right.*

Proof The germ (3.6) with $\varepsilon = 0$ at the origin in the (x, v, p)-space has the form (4.7) with $n = 3$ (Appendix A). Indeed, its components belong to the ideal $I = \langle pA, v\rangle = \langle p, v\rangle$ and the center manifold W^c, given by the equations $p = v = 0$, consists of its singular points. At any singular point sufficiently close to the origin, the spectrum of the linear part of (3.6) is $(1, \frac{1}{2}, 0)$. Then, by Theorem 4.5 (Appendix A), the germ (3.6) at the origin is orbitally smoothly equivalent to

$$(2\xi + \varphi(\zeta)\eta^2)\partial_\xi + \eta\partial_\eta. \tag{3.8}$$

The restriction of the field (3.8) to each invariant leaf $\zeta = \text{const}$ is a resonant node with eigenvalues $2 : 1$ and associated eigenvectors $\partial_v, 2\partial_x + \partial_p$. It has an infinite family Φ of integral curves all with the common tangent direction $2\partial_x + \partial_p$ and a unique integral curve with the tangent direction ∂_v, which coincides with the v-axis and does not correspond to a geodesic.

By Lemma 4.2 (Appendix A), to prove that $\varphi(\zeta)$ vanish on each leaf $\zeta = \text{const}$, it is sufficient to produce a smooth integral curve of the family Φ. We use the integral curve $x = 2p$, $v = 0$ corresponding to the isotropic geodesic $y = \frac{1}{4}x^2$ which is a solution of equation $p^2 = y$. Hence $\varphi(\zeta) \equiv 0$, and the normal form (3.8) becomes

$$2\xi\partial_\xi + \eta\partial_\eta. \tag{3.9}$$

Comparing (3.6) with $\varepsilon = 0$ and (3.8), one can show that the conjugating diffeomorphism $(x, v, p) \mapsto (\xi, \eta, \zeta)$ can be chosen in the form

$$\xi = v, \quad \eta = pf(x, v, p), \quad \zeta = x - 2p + g(x, v, p), \quad f(0) = 1, \quad g \in \mathfrak{M}^1,$$

where $\mathfrak{M}^k$, $k \geq 0$, is the ideal of k-flat functions in the ring of smooth functions.

The field (3.9) has the invariant foliation $\xi = c\eta^2$, $c \in \mathbb{R}P^1 = \mathbb{R} \cup \infty$. Returning to the coordinates (x, v, p), we get the invariant foliation of the field (3.6) given by

$$v = cp^2 f^2(x, v, p), \quad f(0) = 1. \tag{3.10}$$

The value $c = \infty$ corresponds to the invariant plane $\Pi = \{p = 0\}$ which does not give any geodesics. For $c \in \mathbb{R}$, solving (3.10) in v in a neighborhood of the origin gives $v = cp^2\psi_c(x, p)$, where $\psi_c(x, p)$ is a smooth function with $\psi_c(0, 0) = 1$. Returning to the initial variables (x, y, p) by mean of the map Ψ (formula (3.4)), we get the invariant foliation of the field (3.3):

$$y = p^2(1 + cp^2\psi_c(x, p)), \quad \psi_c(0, 0) = 1, \tag{3.11}$$

see Figure 3 (left). The value $c = 0$ corresponds to the isotropic surface $p^2 = y$.

Observe that all invariant leaves of the foliation (3.11) belong to the semiplane $y > 0$. The plane $y = 0$, which does not belong to the foliation (3.11), is an invariant plane of the field (3.3) foliated by the vertical lines, which are integral curves of (3.3).

After dividing by the common factor p^2, the restriction of the field (3.6) to each invariant leaf (3.11) is given by

$$\frac{dp}{dx} = \frac{\widetilde{\omega} - cp^2\psi_c(\widetilde{\omega} + p\widetilde{\omega}_x + y\widetilde{\omega}_y)}{2\widetilde{\omega}(1 + cp^2\psi_c)} = \frac{1}{2} - cp^2(1 + h_c(x,p)), \quad h_c \in \mathfrak{M}^0, \tag{3.12}$$

where $\widetilde{\omega}$, $\widetilde{\omega}_x$, $\widetilde{\omega}_y$ are the restrictions of ω, ω_x, ω_y to the given leaf. In a neighborhood of the origin, (3.12) defines a smooth and regular direction field, and every leaf (3.11) contains a unique smooth integral curve of the field (3.6) passing through the origin in the (x, y, p)-space with the tangent direction ∂_x, see Figure 3 (center). Projecting these integral curves to the (x, y)-plane (equivalently, integrating equation (3.12)), we get a one-parameter family of geodesics in the statement of the theorem with $\alpha = -\frac{c}{48}$, see Figure 3 (right). $\square$

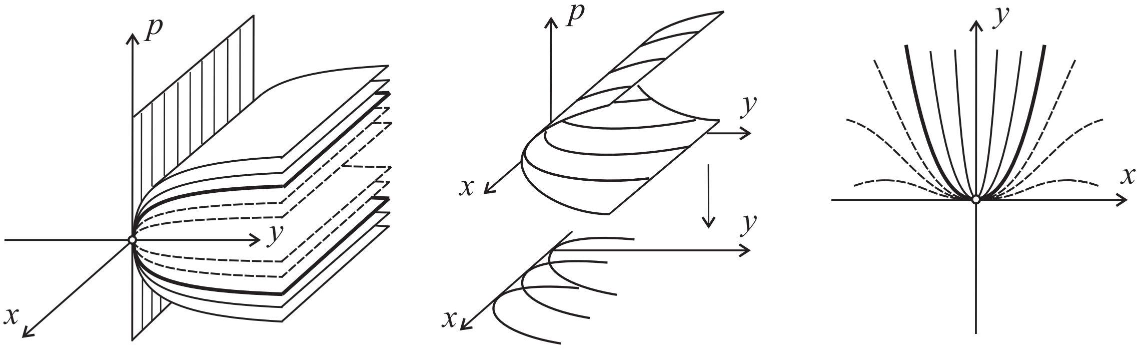

Figure 3: The case Z: invariant foliation (3.11) of the field (3.3) (left), integral curves of (3.3) on an invariant leaf (center) and geodesics $\gamma_\alpha^+ \in \Gamma_0$ (right). Here the discriminant curve $\mathscr{D}$ coincides with the x-axis. Timelike, spacelike and isotropic geodesics are solid, dashed and bold solid lines, respectively.

To illustrate Theorem 3.1, we consider the simplest example $ds^2 = dy^2 - ydx^2$. In this case, equation (2.3) can be studied using qualitative methods, see, for example, [22] (Section 3). The Lagrangian of the length functional $L = \sqrt{p^2 - y}$ does not depend on the variable x, hence the field (2.3) possesses the energy integral $H = L - pL_p$. After evident transformations, equation $H = \text{const}$ can be reduced to

$$p^2 = y - \alpha y^2, \quad \alpha \in \mathbb{R}, \tag{3.13}$$

which is a family of implicit differential equations of Clairaut type.

Every (unparametrized) geodesic in the metric $ds^2 = dy^2 - ydx^2$ is a solution of equation (3.13). Conversely, every solution of (3.13) is a geodesic except the horizontal lines $y \equiv \text{const}$, each of which is the envelop of the family of integral curves of (3.13) for a given α (see [22]). For instance, the value $\alpha = 0$ corresponds to the isotropic surface $p^2 = y$ (a parabolic cylinder) and gives the isotropic geodesic $y = \frac{1}{4}x^2$ passing through the origin. For determining non-isotropic geodesics, observe that every invariant surface (3.13) is a cylinder whose generatrices are parallel to the x-axis and the base is an ellipse (if $\alpha > 0$) or a hyperbola (if $\alpha < 0$). In the last case, the hyperbolic cylinder $p^2 = y - \alpha y^2$ consists of two connected components: *positive* and *negative* lying in the domains $y \geq 0$ and $y \leq \alpha^{-1}$, respectively. See Figure 4, left.

Positive components of the hyperbolic cylinders ($\alpha < 0$) together with all other cylinders ($\alpha \geq 0$) form an invariant foliation of the form (3.10) (Figure 4, left). Negative components of the hyperbolic cylinders do not intersect the plane $y = 0$, and consequently, they do not contain integral curves whose projections to the (x, y)-plane are geodesics passing through the x-axis. Moreover, from (3.13) it follows that $u = y/p^2 = 1/(1 - \alpha y)$, which shows that $u \to 1$ along any geodesic tending to the x-axis with isotropic tangential direction. This gives a graphical explanation why $u = 1$ is the only admissible value of the variable u at $y = p = 0$.

Thus to every $\alpha \geq 0$ corresponds a geodesic $\gamma_\alpha^+ \in \Gamma_0$ which is timelike if $\alpha > 0$ or isotropic if $\alpha = 0$. To every $\alpha < 0$ corresponds a spacelike geodesic $\gamma_\alpha^+ \in \Gamma_0$, whose lift belongs to the positive component of the hyperbolic cylinder $p^2 = y - \alpha y^2$. In contrast to this, the negative component of the same cylinder is filled with integral curves of the field (2.3) whose projections on the (x, y)-plane are separated from the x-axis by the horizontal strip $\alpha^{-1} < y < 0$. See Figure 4, right.

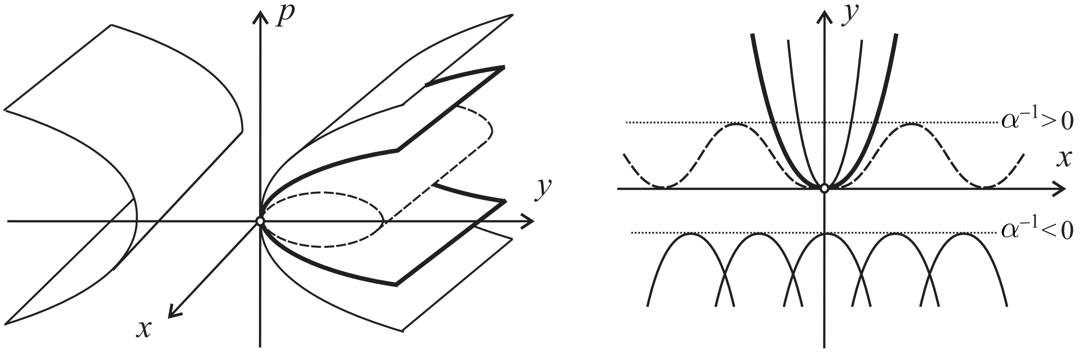

Figure 4: The invariant foliation $p^2 = y - \alpha y^2$ in the (x, y, p)-space (left) and the corresponding geodesics (right). Timelike, spacelike and isotropic geodesics are solid, dashed and bold solid lines, respectively.

3.2 The cases D_s, D_n, D_f

We take the metric as in (3.2) with $\varepsilon \neq 0, \frac{1}{16}$ near the point $q \in \mathscr{D}$. The germ (3.6) with $\varepsilon \neq 0$ at the origin is hyperbolic with the spectrum $(1, \varepsilon_1, \varepsilon_2)$, where $(\varepsilon_1, \varepsilon_2)$ is the spectrum of the field (2.2) at the origin, so $\varepsilon_1 + \varepsilon_2 = \frac{1}{2}$ and $\varepsilon_1 \varepsilon_2 = \varepsilon$. The corresponding eigenvectors are ∂_v, $\partial_x + \varepsilon_1 \partial_p$ and $\partial_x + \varepsilon_2 \partial_p$.

Recall that we assumed that, in the cases D_n, D_s, there are no non-trivial resonances (3.1) between $\varepsilon_1, \varepsilon_2, 1$. Hence, by Theorem 4.1 (Appendix A), the germ (3.6) at the origin is smoothly equivalent to

$$\xi \partial_\xi + \varepsilon_1 \eta \partial_\eta + \varepsilon_2 \zeta \partial_\zeta. \tag{3.14}$$

Remark 3.1 It follows by comparing (3.6) and (3.14) that the conjugating diffeomorphism $(x, v, p) \mapsto (\xi, \eta, \zeta)$ and its inverse can be chosen in the form

$$\begin{aligned} &x = \eta(1 + \varphi_1) + \zeta(1 + \varphi_2), \quad p = \eta(\varepsilon_1 + \varphi_3) + \zeta(\varepsilon_2 + \varphi_4), \quad v = \xi; \\ &\eta = \frac{x(\varepsilon_2 + \psi_1) - p(1 + \psi_2)}{\varepsilon_2 - \varepsilon_1}, \quad \zeta = \frac{x(\varepsilon_1 + \psi_3) - p(1 + \psi_4)}{\varepsilon_1 - \varepsilon_2}, \quad \xi = v; \end{aligned} \tag{3.15}$$

where $\varphi_i = \varphi_i(\xi, \eta, \zeta)$ and $\psi_i = \psi_i(x, v, p)$ are smooth functions vanishing at the origin.

Theorem 3.2 *Let S be a surface with a pseudo-Riemannian metric* (1.1) *and let $q \in \mathscr{D}$ be a point satisfying the conditions D_s in Table 1. Then to the isotropic direction p_0 corresponds a one-parameter family Γ_0 of C^2-smooth geodesics outgoing from q into the Lorenzian domain, while there are no geodesics outgoing from q into the Riemannian domain.*

There exist smooth local coordinates centered at the origin such that the metric has the form (3.2) *and the geodesics $\gamma_\alpha^+ \in \Gamma_0$ outgoing from the origin are*

$$y = \frac{\varepsilon_1}{2} x^2 + Y_\alpha(x), \quad Y_\alpha(x) = o(x^2), \quad \varepsilon_1 > \frac{1}{2}, \quad \alpha \in \mathbb{R}, \tag{3.16}$$

together with the isotropic geodesic

$$y = \frac{\varepsilon_2}{2} x^2 + Y(x), \quad Y(x) = o(x^2), \quad \varepsilon_2 < 0. \tag{3.17}$$

The family (3.16) *contains all three types of geodesics: timelike if $\alpha < 0$, spacelike if $\alpha > 0$ and isotropic if $\alpha = 0$; see* Figure 5, *right.*

Proof By Lemma 4.1 (Appendix A), equation $c_1|\eta|^{1/\varepsilon_1} + c_2|\zeta|^{1/\varepsilon_2} + c_3\xi = 0$ with any constants c_i defines an invariant surface of the field (3.14). Since $\varepsilon < 0$, the eigenvalues ε_1 and ε_2 have different signs. We assume, without loss of generality, that $\varepsilon_1 > \frac{1}{2}$ and

$\varepsilon_2 < 0$. Hence, the invariant surface $c_1|\eta|^{1/\varepsilon_1} + c_2|\zeta|^{1/\varepsilon_2} + c_3\xi = 0$ passes through the origin if and only if $c_1 = c_3 = 0$ or $c_2 = 0$. This yields the invariant foliation

$$\xi = \alpha|\eta|^{1/\varepsilon_1}, \quad \alpha \in \mathbb{R}P^1 = \mathbb{R} \cup \infty, \tag{3.18}$$

where $\alpha = \infty$ corresponds to the plane $\eta = 0$ being the limit set of the cylindric surfaces $\xi = \alpha|\eta|^{1/\varepsilon_1}$ as $\alpha \to \infty$. The restriction of the field (3.14) to each invariant leaf (3.18) is a saddle with the separatrices

$$\begin{aligned}&\{\xi = \eta = 0\} \ \text{ and } \ \{\xi = \alpha|\eta|^{1/\varepsilon_1}, \ \zeta = 0\} \ \text{ for } \ \alpha \neq \infty,\\ &\{\xi = \eta = 0\} \ \text{ and } \ \{\eta = \zeta = 0\} \ \text{ for } \ \alpha = \infty,\end{aligned}$$

where the separatrix $\{\xi = \eta = 0\}$ is the intersection of all invariant leaves (3.18). The corresponding invariant foliation of the field (3.3) is as in Figure 5 (left).

Taking into account (3.15), $u = v + 1$ and $y = \varepsilon x^2 + up^2$, one can see that the separatrix $\{\eta = \zeta = 0\}$ corresponds to the v-axis in the (x, v, p)-space and to the origin in the (x, y, p)-space. The remaining separatrices $\{\xi = \alpha|\eta|^{1/\varepsilon_1}, \zeta = 0\}$ and $\{\xi = \eta = 0\}$ yield the family of integral curves of the field (3.5) passing through the point $(0, 1, 0)$ in the (x, u, p)-space:

$$\{x = \eta(1+\widetilde{\varphi}_{1,\alpha}(\eta)), \ p = \eta(\varepsilon_1 + \widetilde{\varphi}_{3,\alpha}(\eta)), \ u = 1 + \alpha|\eta|^{1/\varepsilon_1}\}, \quad \alpha \in \mathbb{R}, \tag{3.19}$$

$$\{x = \zeta(1 + \widetilde{\varphi}_2(\zeta)), \ p = \zeta(\varepsilon_2 + \widetilde{\varphi}_4(\zeta)), \ u = 1\}, \tag{3.20}$$

where $\widetilde{\varphi}_{i,\alpha}(\eta) = \varphi_i(\alpha|\eta|^{1/\varepsilon_1}, \eta, 0)$ for $i = 1, 3$, and $\widetilde{\varphi}_i(\zeta) = \varphi_i(0, 0, \zeta)$ for $i = 2, 4$. Observe that the integral curve (3.19) with $\alpha = 0$ and the integral curve (3.20) belong to the isotropic surface $\{u = 1\}$.

Since the right-hand sides of $x = \eta(1 + \widetilde{\varphi}_{1,\alpha}(\eta))$ and $x = \zeta(1 + \widetilde{\varphi}_2(\zeta))$ are C^1 and C^∞-smooth respectively, both equations can be solved for η. Hence, from (3.19) and (3.20) one can express the variables p and u as functions of x. To complete the proof, observe that the map $\pi \circ \Psi(x, u, p) = (x, y)$ sends the family of integral curves (3.19) to the family of geodesics (3.16) and the integral curve (3.20) to the geodesic (3.17); see Figure 5 (right). □

Remark 3.2 In the case Z the family Γ_0 given by (3.7) contains a unique isotropic geodesic $y = \frac{1}{4}x^2$ (the bold line in Figure 3, right) which separates Γ_0 into timelike and spacelike geodesics. In the case D_s the family Γ_0 contains two isotropic geodesics, corresponding to the integral curve (3.19) with $\alpha = 0$ and the integral curve (3.20). The first (the bold line in Figure 5, right) separates Γ_0 into timelike and spacelike geodesics, while the second (the double line in Figure 5, right) does not. The difference between the families Γ_0 in the cases Z and D_s is related to topological structure of the invariant foliations of the field (3.3) in the cases Z and D_s; compare Figures 3 (left) and 5 (left). In the case Z all invariant leaves intersect on the line $\Psi(\Pi)$ only, while in the case D_s they intersect on the dotted line $\Psi(\Pi)$ and on the double line which corresponds to $\{\xi = \eta = 0\}$ in the normal form (3.14).

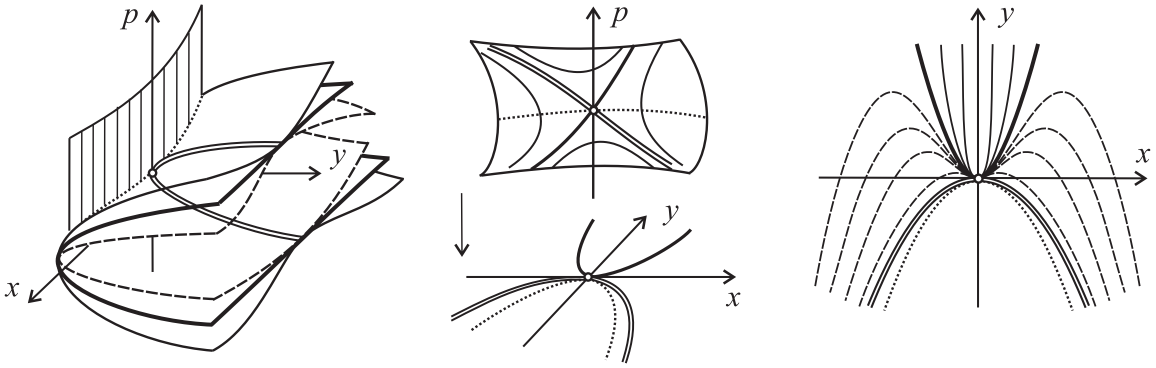

Figure 5: The case D_s: invariant foliation of the field (3.3) (left), integral curves of (3.3) on an invariant leaf (center) and geodesics $\gamma^+_\alpha \in \Gamma_0$ (right). On the right: timelike and spacelike geodesics are solid and dashed lines, respectively. The bold line and the double line are isotropic geodesics, the dotted line is the discriminant curve.

Theorem 3.3 *Let S be a surface with a pseudo-Riemannian metric* (1.1) *and let $q \in \mathscr{D}$ be a point satisfying the conditions D_n or D_f in Table 1. Then to the isotropic direction p_0 corresponds a two-parameter family Γ_0 of C^2-smooth geodesics outgoing from q into the Lorenzian domain, while there are no geodesics outgoing from q into the Riemannian domain.*

There exist smooth local coordinates centered at the origin such that the metric has the form (3.2) *and the field* (3.3) *has the invariant foliation*

$$y = \varepsilon x^2 + p^2(1 + \alpha Y_\alpha(x,p)), \quad Y_\alpha \in \mathfrak{M}^2, \quad \alpha \in \mathbb{R}, \tag{3.21}$$

see Figure 6, left. The restriction of the field (3.3) *to every invariant leaf* (3.21) *is a node* (for D_n) *or a focus* (for D_f) *with spectrum $\varepsilon_1, \varepsilon_2$, and the geodesics $\gamma^+_{\alpha,\beta} \in \Gamma_0$ are projections of the integral curves of* (3.3) *on the leaves* (3.21) *to the (x, y)-plane* (Figure 6, right). *The geodesics $\gamma^+_{\alpha,\beta} \in \Gamma_0$ are timelike if $\alpha < 0$, spacelike if $\alpha > 0$ and isotropic if $\alpha = 0$.*

Proof We start with the question of linearizability of the germ (3.6) at the origin. In the case D_n, the germ (3.6) is smoothly equivalent to the linear normal form (3.14) with $0 < \varepsilon_1, \varepsilon_2 < \frac{1}{2}$ (Theorem 4.1 in Appendix A), and the conjugating diffeomorphism has the form (3.15).

In the case D_f, Theorem 4.1 does not apply because the spectrum $(1, \varepsilon_1, \varepsilon_2)$ with

$$\varepsilon_1 = a + bi, \quad \varepsilon_2 = a - ib, \quad a = \tfrac{1}{4}, \quad b = \tfrac{1}{4}\sqrt{16\varepsilon - 1}, \quad \varepsilon = \varepsilon_1\varepsilon_2 > \tfrac{1}{16}, \tag{3.22}$$

has the resonance $2(\varepsilon_1 + \varepsilon_2) = 1$ of the order $|s| = 4$ impeding the linearizability in the C^4-smooth category. Consider along with (3.1) the resonances obtained by taking the

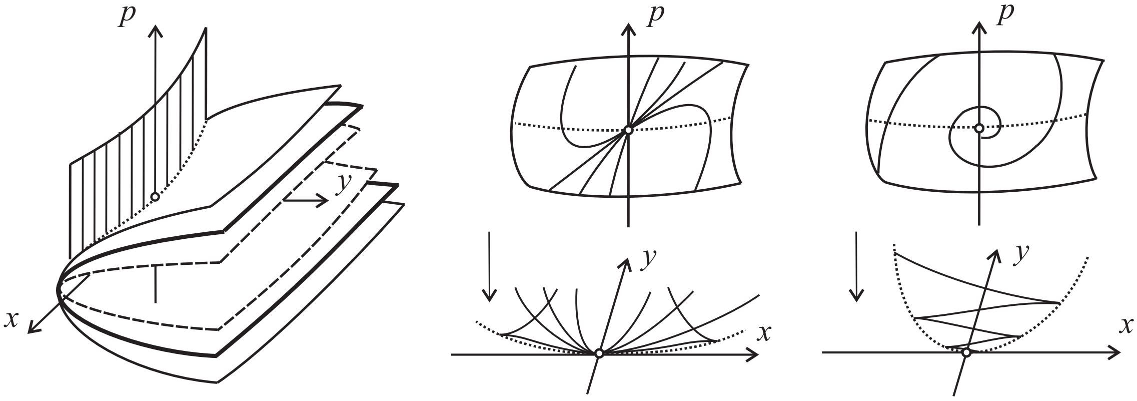

Figure 6: The cases D_n and D_f: invariant foliation of the field (3.3) (left), integral curves of the field (3.3) on an invariant leaf and their projection to the (x, y)-plane in the cases D_n (center) and D_f (right).

real part of both sides of (3.1). The spectrum (3.22) has five resonances of this type of order greater than one: $\mathrm{Re}(s_1\varepsilon_1 + s_2\varepsilon_2) = 1$, $|s| = s_1 + s_2 = 4$. Thus in the case D_f, the germ (3.6) satisfies the condition of Theorem 4.3 (Appendix A) with $k = 1$, and consequently, it is C^1-smoothly equivalent to

$$\xi\partial_\xi + (a\eta + b\zeta)\partial_\eta + (a\zeta - b\eta)\partial_\zeta \tag{3.23}$$

with a, b as in (3.22).

Thus in the case D_n (resp. D_f) the germ (3.6) is C^∞ (resp. C^1) smoothly equivalent to the linear normal form (3.14) (resp. (3.23)), and the conjugating diffeomorphism has the form

$$\begin{aligned} &x = \eta\varphi_1 + \zeta\varphi_2, \quad p = \eta\varphi_3 + \zeta\varphi_4, \quad v = \xi, \\ &\eta = x\psi_1 + p\psi_2, \quad \zeta = x\psi_3 + p\psi_4, \quad \xi = v, \end{aligned} \tag{3.24}$$

for some C^∞ (resp. C^1) smooth functions $\varphi_i = \varphi_i(\xi, \eta, \zeta)$ and $\psi_i = \psi_i(x, v, p)$.

By Lemma 4.1 (Appendix A), equations

$$\xi = \alpha(|\eta|^{1/\varepsilon_1} + |\zeta|^{1/\varepsilon_2}), \tag{3.25}$$

$$\xi = \alpha(\eta^2 + \zeta^2)^2, \tag{3.26}$$

where $\alpha \in \mathbb{R}P^1$, define invariant foliations of the linear fields (3.14) and (3.23), respectively. Here $\alpha = \infty$ gives the ξ-axis in the normal coordinates, i.e., the v-axis in the (x, v, p)-space, and consequently, the origin in the (x, y, p)-space. Hence we shall consider both equations (3.25) and (3.26) with $\alpha \in \mathbb{R}$ only.

Substituting expressions (3.24) for ξ, η, ζ in (3.25) and (3.26), gives the invariant foliation of the field (3.6) in the case D_n and D_f respectively:

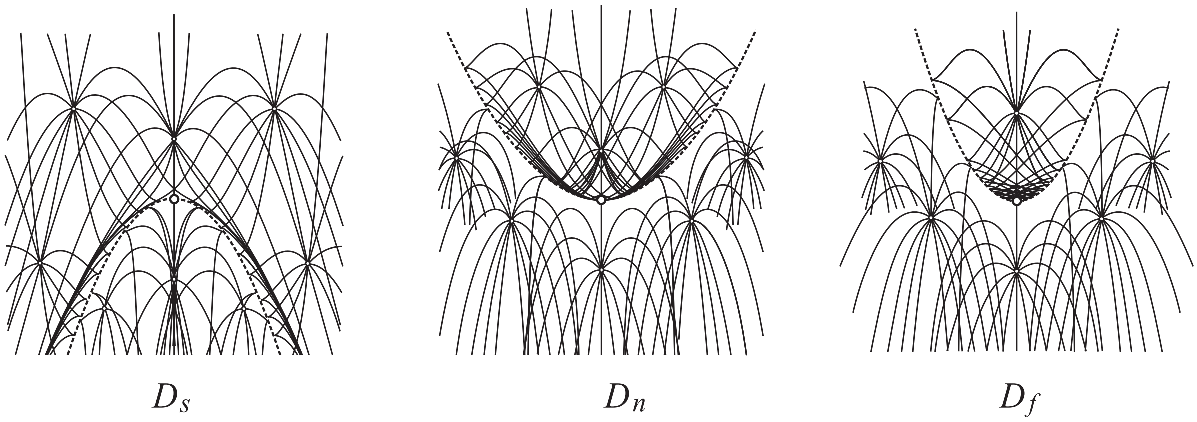
$$v = \alpha\big(|x\psi_1 + p\psi_2|^{1/\varepsilon_1} + |x\psi_3 + p\psi_4|^{1/\varepsilon_2}\big), \tag{3.27}$$

$$v = \alpha\big(|x\psi_1 + p\psi_2|^2 + |x\psi_3 + p\psi_4|^2\big)^2. \tag{3.28}$$

Note that the right-hand sides of (3.27) and (3.28) are at least C^1-smooth (in the case D_n, $0 < \varepsilon_1, \varepsilon_2 < \frac{1}{2}$). By the implicit function theorem, (3.27) and (3.28) can be solved in v near the origin. In both cases we get the equation $v = \alpha Y_\alpha(x, p)$ with a C^1-smooth function Y_α vanishing at the origin. Substituting this expression into $y = \varepsilon x^2 + (1 + v)p^2$, gives the invariant foliation (3.21) of the field (3.3).

Similarly to the case Z, one can divide the restriction of the field (3.3) to every invariant leaf by the common factor p (see formula (3.12)). Then the restriction of the field (3.3) to every invariant leaf (3.21) becomes a node (in the case D_n) and a focus (in the case D_f) with the spectrum $(\varepsilon_1, \varepsilon_2)$ (Figure 6, center, right). □

Figure 7 presents computer generated pictures of geodesics on a surface endowed with the metric (3.2) with $\omega \equiv -1$ and $\Theta \equiv 0$ in the cases D_s, D_n, D_f.



D_s D_n D_f

Figure 7: Geodesics (solid lines) in the metric (3.2) with $\omega \equiv -1$ and $\Theta \equiv 0$ in the cases D_s (left), D_n (center), D_f (right). The dotted line is the discriminant curve.

4 Appendix A. Local normal forms of vector fields

Here we give a brief survey of local normal forms for vector fields in real phase space, which were used in this paper (for more details, see also surveys in [2, 3]). All vector fields are supposed to be smooth (that means C^∞ unless stated otherwise). By C^ω we denote the class of analytic mappings. For convenience, we also present vector fields as autonomous differential equations, where the differentiation is by an auxiliary parameter playing a role of time.

Definition 4.1 Two vector fields V_1 and V_2 are C^k-smoothly (resp. topologically) equivalent, if there exists a C^k-diffeomorphism (resp. homeomorphism) $h\colon \mathbb{R}^n \to \mathbb{R}^n$ that conjugates their phase flows g_1^t and g_2^t, i.e., $h \circ g_1^t = g_2^t \circ h$. Here k is an integer number (finite-smooth equivalence) or ∞ (infinite-smooth equivalence) or ω (analytic equivalence).

Definition 4.2 Two vector fields V_1 and V_2 are *orbitally* C^k-smoothly (resp. topologically) equivalent, if there exists a C^k-diffeomorphism (resp. homeomorphism) that conjugates their integral curves (orbits of their phase flows).

Remark 4.1 The second definition slightly differs from the generally accepted definition of the orbital equivalence, where coincidence of the orientation of integral curves is also required. In fact, our definition is naturally related to directions fields, whose integral curves do not have a orientation a priori.

A great deal of work is done to bring a vector field to a normal form in a neighborhood of its singular point under a chosen equivalence relation. In particular, the germ of a vector field at its singular point is called *linearizable* (in a certain category) if it is equivalent (in this category) to its linear part. Of course, not all vector fields are linearizable, and when it is not, the question is what normal formal can we get.

Definition 4.3 Let V be the germ of a vector field with singular point the origin 0 in $\mathbb{R}^n$ and $\lambda = (\lambda_1, \dots, \lambda_n) \in \mathbb{C}^n$ be the spectrum of V at 0. The germ V is called *hyperbolic* if the spectrum λ does not contain neither zeros nor pure imaginary eigenvalues. The germ V is called *partially hyperbolic* if the spectrum λ contains at least one eigenvalue with non-zero real part.

4.1 Hyperbolic germs

Let V be the germ of a hyperbolic vector field at 0. For topological equivalence the only local invariants are the scalars $a_i = \operatorname{sgn}(\operatorname{Re}\lambda_i)$. The Grobman-Hartman Theorem [2, 11] states that V is topologically equivalent to the field $\dot\xi_i = a_i\xi_i$, $i = 1, \dots, n$.

For the C^k-smooth equivalence, resonances of two types play an important role:

$$\lambda_j - (s, \lambda) = 0, \quad s_i \in \mathbb{Z}_+, \quad j \in \{1, \dots, n\}, \tag{4.1}$$

$$\operatorname{Re}(\lambda_j - (s, \lambda)) = 0, \quad s_i \in \mathbb{Z}_+, \quad j \in \{1, \dots, n\}, \tag{4.2}$$

where $(s, \lambda) = s_1\lambda_1 + \cdots + s_n\lambda_n$ is the standard scalar product. In both relations (4.1), (4.2) the natural number $|s| = s_1 + \cdots + s_n$ is called the *order* of the resonance, and $\xi^s = \xi_1^{s_1} \cdots \xi_n^{s_n}$ is called the *resonant monomial.* In general, non-trivial resonances (4.1), (4.2) of orders $|s| \geq 2$ are obstacles for the germ V to be C^k-smoothly linearizable.

Theorem 4.1 ([2, 4, 29]) *If the spectrum* λ *does not have resonances* (4.1) *of any order* $|s| \geq 2$*, the germ* V *is* C^∞*-smoothly linearizable. Moreover, if* $\lambda \in \mathbb{R}^n$ *and has only trivial resonances* (4.1)*, the germ* V *is* C^∞*-smoothly equivalent to*

$$\dot{\xi}_i = \lambda_i \xi_i, \quad i = 1, \ldots, n. \tag{4.3}$$

Theorem 4.2 ([2, 4, 11]) *If* $\lambda \in \mathbb{R}^n$*, then the germ* V *is* C^∞*-smoothly equivalent to the field*

$$\dot{\xi}_i = \lambda_i \xi_i + \sum_{s \in \mathbb{Z}^n_+} a_{is} \xi^s, \quad i = 1, \ldots, n. \tag{4.4}$$

where $a_{is} \neq 0$ *only if the resonance* (4.1) *holds.*

In other words, Theorems 4.1 and 4.2 states that the normal forms (4.3), (4.4) contain resonant monomials only. Here the linear terms $\lambda_i \xi_i$ correspond to trivial resonances (4.1), while all remaining terms $a_{is}\xi^s$ correspond to non-trivial resonances (4.1) if they exist. Under some additional restrictions, Theorems 4.1, 4.2 are valid in C^ω category. For instance, in the case $\lambda \in \mathbb{R}^n$ it is sufficient to require that all λ_i have the same sign. However, if λ_i have different signs, the restrictions are much stronger, especially if λ has non-trivial resonances (Theorem 4.2), see [2, 3] and the references therein.

On the contrary, requirements become weaker if we consider C^k-smooth equivalence with $k < \infty$, see e.g. [2, 25, 26]. In this paper, we need the following result.

Theorem 4.3 ([2, 27]) *Suppose that for some positive integer* k *the spectrum* λ *has neither resonances* (4.1) *of order* $2 \leq |s| \leq 2k$ *nor resonances* (4.2) *of order* $|s| = 2k$*. Then* V *is* C^k*-smoothly linearizable.*

We establish below the existence of invariant foliations of a hyperbolic linear vector field in 3-dimensional real phase. Assume, without loss of generality, that one of the eigenvalues λ_i of is equal to 1. It is sufficient to consider the following two fields

$$\dot{\xi}_1 = \lambda_1 \xi_1, \quad \dot{\xi}_2 = \lambda_2 \xi_2, \quad \dot{\xi}_3 = \xi_3, \tag{4.5}$$

$$\dot{\xi}_1 = (\alpha \xi_1 + \beta \xi_2), \quad \dot{\xi}_2 = (\alpha \xi_2 - \beta \xi_1), \quad \dot{\xi}_3 = \xi_3, \tag{4.6}$$

where λ_1, λ_2 and α, β are real and non-zero.

Lemma 4.1 *For any real constants* c_i *the equations*

$$c_1 |\xi_1|^{1/\lambda_1} + c_2 |\xi_2|^{1/\lambda_2} + c_3 \xi_3 = 0,$$

$$c_1 (\xi_1^2 + \xi_2^2)^{1/2\alpha} + c_3 \xi_3 = 0,$$

define invariant surfaces of the fields (4.5) *and* (4.6)*, respectively,*

The proof is trivial and is omitted.

4.2 Partially hyperbolic germs

Let W^s, W^u, W^c be the unstable, stable and center manifold of the partial hyperbolic germ V at 0, and let $d_i = \dim W^i$, $i = s, u, c$. Set $d = d_s + d_u$, then $d, d_c > 0$ and $d + d_c = n$. One can choose local coordinates $(\xi_1, \dots, \xi_{d_s}) \in W^s$, $(\xi_{d_s+1}, \dots, \xi_d) \in W^u$, $\zeta = (\zeta_1, \dots, \zeta_{d_c}) \in W^c$.

Theorem 4.4 ([2, 12]) *The germ V is topologically equivalent to the direct product of d-dimensional standard saddle (the first d equations) and the restriction of V to the center manifold (the last d_c equations):*

$$\dot{\xi}_i = \xi_i, \ \ i = 1, \dots, d_s; \quad \dot{\xi}_i = -\xi_i, \ \ i = d_s + 1, \dots, d;$$
$$\dot{\zeta}_j = Z_j(\zeta), \ \ j = 1, \dots, d_c.$$

In this paper, we deal with a special class of partially hyperbolic vector fields, which were studied by many authors, see e.g. [23, 31]. From now on, we assume that all components of the germ V belong to the ideal I (in the ring of smooth functions vanishing at 0) generated by two of them.

More specifically, such a germ V has the form

$$\dot{\xi} = v, \quad \dot{\eta} = w, \quad \dot{\zeta}_j = \alpha_j v + \beta_j w, \quad j = 1, \dots, n-2, \tag{4.7}$$

where v, w and α_j, β_j are smooth functions of the variables ξ, η, ζ_j. The components of the germ (4.7) belong to the ideal $I = \langle v, w \rangle$, and the spectrum of V contains at most two non-zero eigenvalues: $\lambda = (\lambda_1, \lambda_2, 0, \dots, 0)$.

We shall further assume that $\operatorname{Re}\lambda_1 \neq 0$ and $\operatorname{Re}\lambda_2 \neq 0$. Hence the center manifold $W^c = \{v = w = 0\} \subset \mathbb{R}^n$ is a smooth manifold of codimension 2 and the restriction of the field V to W^c is identically zero, so W^c consists of singular points of V. By Theorem 4.4, the germ V is topologically equivalent to

$$\dot{\xi} = a_1 \xi, \quad \dot{\eta} = a_2 \eta, \quad \dot{\zeta}_j = 0, \quad j = 1, \dots, n-2,$$

where $a_i = \operatorname{sgn}(\operatorname{Re}\lambda_i)$, $i = 1, 2$.

For C^k-smooth classification of the germ (4.7), we need to introduce two types of resonances between the non-zero eigenvalues λ_1, λ_2 being, in fact, partial cases of (4.1):

$$s_1\lambda_1 + s_2\lambda_2 = 0, \quad s_i \in \mathbb{Z}_+, \quad i = 1, 2, \tag{4.8}$$
$$s_1\lambda_1 + s_2\lambda_2 = \lambda_j, \quad s_i \in \mathbb{Z}_+, \quad i, j = 1, 2. \tag{4.9}$$

For simplifying the presentation, further we shall always assume that $|\lambda_1| \geq |\lambda_2|$ and exclude from consideration trivial resonances (4.8) ($s_1 = s_2 = 0$) and (4.9) ($s_1 = 1$,

$j = 1$ or $s_2 = 1$, $j = 2$). Then the absence of resonances (4.9) implies the absence of (4.8). On the other hand, in the absence of (4.8), resonances (4.9) may have only the form $\lambda_1 = m\lambda_2$, for positive integers m.

Given the germ (4.7) with $\operatorname{Re}\lambda_1 \neq 0$ and $\operatorname{Re}\lambda_2 \neq 0$ we choose local coordinates ξ, η (called *hyperbolic variables*) and $\zeta = (\zeta_1, \ldots, \zeta_{n-2}) \in W^c$ (called *non-hyperbolic variables*) such that the ideal $I = \langle \xi, \eta \rangle$, and consequently, the center manifold W^c is given by $\xi = \eta = 0$. The linearization of V with respect to the hyperbolic variables has two eigenvalues which are continuous functions $\lambda_1(\zeta)$ and $\lambda_2(\zeta)$ of $\zeta \in W^c$. We have $\lambda_j(0) = \lambda_j$, $j = 1, 2$ and λ_j as above.

An analogue of Theorems 4.1 and 4.2 is the following.

Theorem 4.5 ([10, 23]) *Suppose that between* $\lambda_1(\zeta)$ *and* $\lambda_2(\zeta)$ *there are no non-trivial resonances* (4.8) *of any order* $|s| \geq 1$ *for all* ζ *sufficiently close to zero. Then the germ* (4.7) *is* C^∞*-smoothly equivalent to*

$$\dot{\xi} = X, \quad \dot{\eta} = Y, \quad \dot{\zeta}_j = 0, \quad j = 1, \ldots, n-2, \tag{4.10}$$

where X, Y *are smooth functions of* ξ, η, ζ_j *such that the ideal* $I = \langle X, Y \rangle = \langle \xi, \eta \rangle$. *Moreover, if in addition the eigenvalues* $\lambda_1, \lambda_2 \in \mathbb{R}$, *then*

$$X = \lambda_1(\zeta)\xi + \varphi(\zeta)\eta^m, \quad Y = \lambda_2(\zeta)\eta, \tag{4.11}$$

where $\varphi(\zeta) \not\equiv 0$ *only if* $\lambda_1 = m\lambda_2$ *with some natural* $m \geq 1$.

Remark 4.2 If the pair (λ_1, λ_2) belongs to the Poincaré domain (i.e., λ_1 and λ_2 are real and of the same sign or complex conjugate), then the condition

$$s_1\lambda_1(\zeta) + s_2\lambda_2(\zeta) \neq 0, \quad \forall\, s_i \in \mathbb{Z}_+, \quad i = 1, 2, \quad \forall\, \zeta \in W^c, \tag{4.12}$$

follows from (4.8). Moreover, in this case Theorem 4.5 is valid in C^ω category. However, if the pair (λ_1, λ_2) belongs to the Siegel domain (i.e., λ_1 and λ_2 are real and of different signs), the condition (4.12) is equivalent to $\lambda_1(\zeta) : \lambda_2(\zeta) \equiv \text{const}$ for all $\zeta \in W^c$.

The conditions in Theorem 4.5 become weaker if we consider C^k-smooth equivalence with $k < \infty$. Set

$$N(k) = 2\left[(2k+1)\frac{\max|\operatorname{Re}\lambda_{1,2}|}{\min|\operatorname{Re}\lambda_{1,2}|}\right] + 2, \quad k \in \mathbb{N},$$

where the square brackets is the integer part of a number.

Theorem 4.6 ([10, 25]) *For any* $k \in \mathbb{N}$, *the statements in Theorem 4.5 still hold true if* C^∞ *is replaced with* C^k *and the inequalities* $1 \leq |s|$, $1 \leq m$ *are replaced with* $1 \leq |s| \leq N(k)$, $1 \leq m \leq N(k)$ *respectively.*

The normal form (4.10), (4.11) can be further simplified. For our purposes, we are interested in orbital normal form in the case when the resonance $\lambda_1(\zeta) = m\lambda_2(\zeta)$ holds at all $\zeta \in W^c$. Then, dividing by $\lambda_2(\zeta)$, from (4.10), (4.11) we get the orbital normal form

$$\dot{\xi} = (m\xi + \psi(\zeta)\eta^m), \quad \dot{\eta} = \eta, \quad \dot{\zeta}_j = 0, \quad j = 1, \ldots, n-2. \tag{4.13}$$

where the smooth functions $\varphi(\zeta)$ and $\psi(\zeta)$ vanish simultaneously.

The following lemma gives a simple geometric criterion for $\psi(\zeta) \equiv 0$, which is important for applications.

Lemma 4.2 *Let V be the germ of a field from Theorem 4.5 with the normal form (4.10), (4.11) and the resonance $\lambda_1(\zeta) = m\lambda_2(\zeta)$, $m > 1$, holds at all points $\zeta \in W^c$. Then in the orbital normal form (4.13), $\psi(\zeta) = 0$ if and only if V has a C^m-smooth integral curve that passes through the corresponding point $\zeta \in W^c$ with the tangential direction parallel to the eigenvector with $\lambda_2(\zeta)$.*

Proof The field (4.13) can be integrated explicitly. It has the invariant foliation $\zeta = \text{const}$ and each leaf contains a single integral curve $\eta = 0$ with tangential direction ∂_ξ and one-parameter family of integral curves

$$\xi = \eta^m(c + \psi(\zeta)\ln|\eta|), \quad c = \text{const}, \tag{4.14}$$

with the common tangential direction ∂_η at the point $\xi = \eta = 0$. All the curves (4.14) are C^{m-1}-smooth at $\xi = \eta = 0$ if $\varphi(\zeta) \neq 0$ and C^∞-smooth at zero if $\varphi(\zeta) \equiv 0$.

Given $\zeta \in W^c$, the existence of at least one C^m-smooth integral curve passing through the point $\xi = \eta = 0$ (the intersection of W^c with the corresponding invariant leaf $\zeta = \text{const}$) with the tangential direction parallel to the eigenvector with $\lambda_2(\zeta)$ is equivalent to the condition $\psi(0) = 0$. □

Theorem 4.7 ([10, 23]) *Suppose that the resonance $\lambda_1(\zeta) + \lambda_2(\zeta) = 0$ holds at all singular points $\zeta \in W^c$ and $\operatorname{Re}\lambda_1 \neq 0$, $\operatorname{Re}\lambda_2 \neq 0$. Then, for any natural k, the germ V is C^k-smoothly equivalent to*

$$\begin{gathered}\dot{\xi} = \xi(\lambda_1(\zeta) + \rho\Phi_1(\rho,\zeta)), \quad \dot{\eta} = \eta(\lambda_2(\zeta) + \rho\Phi_2(\rho,\zeta)), \\ \dot{\zeta}_j = \rho\Psi_j(\rho,\zeta), \quad j = 1, \ldots, n-2,\end{gathered} \tag{4.15}$$

where $\Phi_i(\rho,\zeta)$ and $\Psi_j(\rho,\zeta)$ are polynomials in $\rho = \xi\eta$ of degrees $N(k) - 1$.

If $\Psi_j(0,0) \neq 0$ for at least one $j = 1, \ldots, n-2$, then the germ V is C^∞-smoothly orbitally equivalent to

$$\dot{\xi} = \xi, \quad \dot{\eta} = -\eta, \quad \dot{\zeta} = \xi\eta, \quad j = 1, \ldots, n-2. \tag{4.16}$$

Theorem 4.7 is not valid in C^ω category.

5 Appendix B. Naturally parametrized geodesics

Naturally parametrized geodesics can be defined as extremals of the action functional

$$J(\gamma) = \int\limits_{\gamma} \big(a\dot{x}^2 + 2b\dot{x}\dot{y} + c\dot{y}^2\big)\, dt, \quad \dot{x} = \frac{dx}{dt}, \;\; \dot{y} = \frac{dy}{dt},$$

where $\gamma \subset S$ is a differentiable curve. The corresponding Euler-Lagrange equation reads

$$\begin{cases} 2(a\ddot{x} + b\ddot{y}) = (c_x - 2b_y)\dot{y}^2 - 2a_y\dot{x}\dot{y} - a_x\dot{x}^2, \\ 2(b\ddot{x} + c\ddot{y}) = (a_y - 2b_x)\dot{x}^2 - 2c_x\dot{x}\dot{y} - c_y\dot{y}^2. \end{cases} \tag{5.1}$$

The definition of geodesics as auto-parallel curves in the Levi-Civita connection generated by the metric (1.1) leads to the same equation (5.1). Equation (5.1) defines a direction field on the tangent bundle TS. The standard projectivization $TS \to PTS$ sends this direction field to the field parallel to (2.3), see [22].

Firstly, using equation (5.1) of parametrized geodesics, we prove the omitted statement in the case Z that the line $\Psi(\Pi) = \{y = p = 0\}$ does not correspond to a geodesic. Recall that in the case Z there exist local coordinates such that

$$ds^2 = (y\omega + \ldots)dx^2 + (0 + \ldots)dxdy - (\omega + \ldots)dy^2, \quad \omega(0,0) = -1.$$

where the dots mean terms that belong to the ideal $\mathfrak{M}^\infty(y)$.

Using appropriate change of variables $y \mapsto yu(x,y)$, where u is a solution of equation $cu_x + b/y = 0$ with the condition $u(0,0) \neq 0$, one can bring locally the metric to the diagonal form $ds^2 = adx^2 + cdy^2$ with the coefficients $a = yu\omega + \ldots$ and $c = -\omega(u + yu_y)$. Substituting $y \equiv b \equiv 0$ into the second equation of (5.1), we get $a_y(x,0)\dot{x}^2 = 0$. Since $a_y(0,0) \neq 0$, this yields $\dot{x} \equiv 0$, and the restriction of the system (5.1) to $y = 0$ has only constant solutions, which are not geodesics.

At first sight it contradicts the fact established in [10]: $\mathscr{F}$ is an invariant surface of the field (2.3), and consequently, any trajectory of (2.3) that lies entirely in $\mathscr{F}$ after the projection on the (x,y)-plane gives a geodesic or a point. (Example: for the metric $ydx^2 - dy^2$ the isotropic surface $p^2 = y$ is filled with one-parameter family of integral curves intersecting $\Psi(\Pi)$ transversally. Projecting this family down, we get the isotropic geodesics $y = \frac{1}{4}(x-c)^2$.) In fact, there is no contradiction: the curve $\Psi(\Pi) \subset \mathscr{F}$ consists of singular points of the field (2.3), and every such a point is a trajectory of (2.3).

Consider the family Γ_0 of geodesics outgoing from a point $q \in \mathscr{D}$ with the isotropic direction p_0. Choose the natural parametrization so that the motion along geodesics proceeds toward q. In the paper [22], it was proved that in the cases C_1, C_3 any geodesic $\gamma \in \Gamma_0$ incomes into the point q in finite time with infinite velocity. The same statement is valid in the case C_2, since it deals with the root p_0 only.

In the case Z, the same result follows from the asymptotic formula established in Theorem 5.1 below. The cases D_s, D_n can be considered similarly, the case D_f is excluded from consideration, since every geodesic $\gamma \in \Gamma_0$ intersects the discriminant curve $\mathscr{D}$ infinite number of times in any neighborhood of q.

Theorem 5.1 *The natural parametrization of geodesics* (3.7) *is given by the formula* $x = t^{\frac{1}{3}}\big(1 + X_\alpha(t^{\frac{1}{3}})\big)$*, where* $X_\alpha(\cdot)$ *are smooth functions vanishing at zero.*

Proof Choosing the local coordinates in Theorem 3.1, from the formula (3.7) we have $y = \frac{1}{4}x^2 + O(x^4)$, $\dot{y} = (\frac{1}{2}x + O(x^3))\dot{x}$, and $\ddot{y} = (\frac{1}{2}x + O(x^3))\ddot{x} + (\frac{1}{2} + O(x^2))\dot{x}^2$. Substituting these expressions together with the coefficients a, b, c from (3.2) into the first equation in (5.1), after a straightforward transformation we obtain

$$\frac{\ddot{x}}{\dot{x}} = \Big(-\frac{2}{x} + f_\alpha(x)\Big)\dot{x}, \tag{5.2}$$

where $f_\alpha(x)$ are smooth functions.

Equation (5.2) defines the natural parametrization uniquely up to non-degenerate affine transformations of the t-axis. Integrating it, we get $\ln|\dot{x}| = -2\ln|x| + F_\alpha(x) + C$, and $\dot{x} = Kx^{-2}e^{F_\alpha(x)}$, where F_α is the primitive of f_α. Without loss of generality put $F_\alpha(0) = 0$ and $K = \frac{1}{3}$ (this corresponds to the choice of the initial velocity of motion along the geodesic). Then we arrive at the differential equation $\frac{dt}{dx} = 3x^2e^{-F_\alpha(x)}$, whose general solution is $t = x^3(1 + T_\alpha(x)) + t_0$, where $T_\alpha(x)$ is a smooth function vanishing at zero. Setting $t_0 = 0$ and inverting, we get $x = t^{\frac{1}{3}}\big(1 + X_\alpha(t^{\frac{1}{3}})\big)$. □

As an example, for the metric $ds^2 = dy^2 - ydx^2$ the system (5.1) reads $y\ddot{x} = -\dot{x}\dot{y}$, $2\ddot{y} = -\dot{x}^2$. Substituting here the isotropic geodesic $y = \frac{1}{4}x^2$, we get $x = k(t - t_0)^{\frac{1}{3}}$. Substituting $y = 0$ (the line $\Psi(\Pi)$), we get $\dot{x} = 0$, that is, $y = 0$ is not a geodesic as was stated above.
